Abstract

AIM: The aim of the study was to evaluate and compare the effect of different access cavity designs, using cone-beam computed tomography (CBCT), on root canal transportation, and centralization performed on two rooted maxillary premolars.

METHODS: Twenty maxillary premolars were randomly divided into two groups. In Group 1, traditional endodontic cavities (TECs) were prepared. In Group 2, contracted endodontic cavities (CECs) were prepared. Mechanical preparation was done by HyFlex electrical discharge machining (EDM) single file in both groups. CBCT imaging was performed pre- and post-root canal preparation for calculations of root canal transportation and centering ability.

RESULTS: Data were analyzed using Mann–Whitney U test and Kruskal–Wallis test. For transportation, teeth with CECs showed the statistically significantly highest median amount of transportation, while as for centering ability, results showed no significant difference between both groups.

CONCLUSION: Under the conditions of this study, HyFlex EDM prepared canals with different access cavity designs without significant shaping errors. TEC showed less transportation than CEC, while both TEC and CEC had no effect on the file centering ability.

Introduction

Endodontic access cavity is a crucial step to ensure that all root canals are properly cleaned, shaped, and filled [1] by enhancing both canal detection and instrumentation effectiveness through elimination of coronal interferences [2]. As an alternative to the traditional endodontic access cavities (TECs), minimally invasive endodontic cavities or contracted endodontic cavities (CECs) have been recently presented in the endodontic literature [3], [4], [5], stressing on the significance of maintaining the integrity of the tooth structure, and conserving the pericervical dentin. While contracted access cavities aims mainly to preserve tooth structure, however the limited accessibility and coronal interference may lead to endodontic instruments to function mostly on the root canal’s internal surface, resulting in root canal transportation that negatively affects long-term prognosis due to excessive removal of dentin and straightening of the original root canal curvature [6], [7]. New generations of NiTi rotary instruments have recently been introduced, with higher flexibility and greater cutting efficiency. HyFlex electrical discharge machining (HFEDM) rotary NiTi file system is submitted to controlled memory (CM) treatment, which has been shown to significantly increase flexibility and resistance to cyclic fatigue. HFEDM is currently the only instrument developed by electrical discharge machining (EDM), the design is distinguished by a variable cross section, shifting from a triangular cross section at the shaft side which provide more flexibility and fatigue resistance to rectangular at the tip (yielding higher torsional resistance) [8]. Despite the different instrument designs and metallurgical advancements, root canal preparation is negatively influenced by the anatomical variation of root canals [7].

The root form and canal anatomy of maxillary first premolars are highly variable. The most common anatomical features include two roots, narrow furcation entrances, deep mesial concavities and the presence of the palatal furcation groove of the buccal root, which is a developmental depression located at the palatal aspect of the buccal root [9]. Lack of knowledge about
the extent and thickness of the dentin in this area might lead to excessive thinning of the dentinal wall during endodontic procedure [10].

The preservation of dentin with CECs preparation can be guided using cone beam computed tomography (CBCT) technology as pre-access analyses can provide information regarding the number root canals and their orientation within the tooth. It can also identify the presence of complex anatomy such as developmental anomalies, isthmuses, and the presence buccolingually broad canals, which if taken into consideration before the access preparation, would lead to increasing the precision of CECs preparation [11].

Therefore, the aim of the present study was to compare the effect of different access cavity designs on root canal transportation and instrument centralization performed on two rooted maxillary premolars using CBCT. The null hypothesis tested was that there would be no influence of the type of endodontic cavity on any of the outcomes investigated.

Materials and Methods

Sample size calculation

The sample size was calculated based on previous studies comparing TECs and CECs [12], [13], both with ten teeth per group. Accordingly, using alpha (α) level of 0.05 and study power = 80%, the minimum estimated sample size was (10) per group giving a total of 20 samples.

Sample selection and grouping

After the approval of a local ethics committee of Faculty of Dentistry, Minia University, a total of 20 intact, mature human two-rooted maxillary premolars extracted for orthodontic or periodontal reasons with similar length and a degree of curvature ranging between 10° and 24° were selected and stored in 0.9% saline solution at 4°C until use[14]. Degree of curvature was measured using Schneider’s technique [15] in which teeth were radiographed buccolingually, two lines were used to measure the angle of curvature, the first was drawn parallel to long axis of the canal, the second one was drawn from the apical foramen to intersect with the first at the point where the canal began to leave the long axis of the tooth, the acute angle formed was measured, and the angle of curvature was determined. Teeth that showed calcification, open apices, previous endodontic treatment teeth or resorption (internal or external resorption) after radiographic examination were excluded from the study. Group allocation was performed randomly into two groups (n = 10 per group) using a random group allocation online software (https://www.randomizer.org) where only the buccal root was considered in the study. The two groups were allocated based on the type of endodontic access preparation; Group I: Traditional endodontic access design, and Group II: Contracted endodontic access design. All teeth were fixed by mounting them vertically halfway in transparent auto polymerizing acrylic resin (Acrostone, Dental and Medical Supplies, Cairo, Egypt) mixed according to the manufacturer’s instructions, and then scanned by CBCT before instrumentation.

Group I: TECs

Endodontic access cavities were drilled with high-speed diamond burs (BR-41 Round bur, Mani, Japan) followed by Endo Z drill (Dentsply Maillefer, Ballaigues, Switzerland) according to conventional access cavity principles described in the literature [16], [17]. The roof of the chamber was removed; the path to canal orifices was unimpeded and unobstructed, providing a straight-line access (Figure 1).

Group II: CECs

Endodontic access cavities were drilled with high-speed diamond burs (BR-41 Round bur, Mani, Japan). The teeth were accessed at the central fossa with minimal extension enough to detect canal orifices, to preserve pericervical dentin as well as part of the chamber roof[18], [19] (Figure 2a and b).

Root canal preparation

The apical patency of all root canals was confirmed using a #10 K-file (Dentsply Maillefer, Ballaigues, Switzerland). Working length was determined using a #10 K-file (Dentsply Maillefer, Ballaigues, Switzerland), which was introduced into the root canal until it became visible at the apical foramen. Working length was set to 1 mm short of...
the apex. 25/~ HyFlex EDM one file system (Coltene, Whaledent, Cuyahoga Falls, OH, USA) was used for shaping the canals of both groups. All instruments were driven using the X-Smart Plus (Dentsply Maillefer, Baillagues, Switzerland). The files were operated at 400-rpm speed and torque of 2 Ncm. Each of the files was used to shape a maximum of four root canals, root canals were irrigated with 2 mL 5.25% sodium hypochlorite (CanalPro; Coltene/Whaledent, Allstetten, Switzerland) solution, 2 mL 17% EDTA (CanalPro; Coltene/Whaledent, Allstetten, Switzerland) were used to remove the smear layer, followed by 2 mL saline and then 2 mL 5.25% sodium hypochlorite were used as a final irrigation and dried with paper points. A single experienced endodontist (A.B) performed all access cavities preparation and instrumentation to avoid inter-operator variability, all steps were done under magnification (4.3× magnification EyeMag Smart Loupes; Carl Zeiss Meditec; Jena, Germany).

**Image capture**

Root canal transportation and instrument centralization were measured both pre and post mechanical preparation at the level of 3 mm, 6 mm, and 9 mm from the apex. The sagittal and coronal views were used to adjust the orientation of the measuring planes, while the measurements were carried out in the axial view. Navigation in the axial plane started at the most extreme point of the root apex and continued for 3 mm, 6 mm, and 9 mm. CBCT images were obtained using a Vatech Pax-i3D Green scanner (VATECH GREEN Inc., Hwaseong-si, Gyeonggi, Korea) with the following settings: Field of view of 50 mm × 50 mm, voxel of 0.080 mm, tube voltage of 94 kVp, tube current of 10 mA, and exposure time of 12.2 s. Images were examined using the scanner’s proprietary software (EZ3d-I, VATECH GREEN Inc., Hwaseong-si, Gyeonggi, Korea). All teeth were scanned using the same CBCT machine with the same exposure settings.

**Evaluation of canal transportation and centering ability**

The formula introduced by Gambill et al. [20] was used to measure the degree of canal transportation. ((x1−x2)−(y1−y2)), where x1 and x2 were the shortest pre-instrumentation and post-instrumentation mesial distance, respectively, y1 and y2 were the shortest pre-instrumentation and post-instrumentation distal distance, respectively. The result of “0” indicates no canal transportation and other than “0” means that transportation has occurred. The following formula was used for the calculation of centering ability, (x1−x2)/(y1−y2) or (y1−y2)/(x1−x2). If the numbers are not equal, the lower figure was considered as the numerator and a result of “1” indicates perfect centering (Figure 3). A second examiner (R.H) who was blinded to all experimental groups performed the measurements (Figure 4). Each specimen had two measurements for reliability.

**Figure 4: Representative cone-beam computed tomography images in axial view for traditional endodontic access cavity group used to evaluate transportation and centering ability, (a to c) before and (d to f) after instrumentation at 3 mm (a and d), 6 mm (b and e), and 9 mm (c and f)**

**Statistical analysis**

Data were explored for normality using Kolmogorov–Smirnov test and showed non-parametric
distribution. Data were described using minimum, maximum, median, and inter-quartile. Comparisons were carried out between two studied independent not-normally distributed subgroups using Mann–Whitney U test and between more than two studied independent not-normally distributed subgroups using Kruskal–Wallis test. Post hoc pair-wise comparisons when Kruskal–Wallis test was significant were carried out using Dunn-Sidak test for multiple comparisons. An alpha level was set to 5% with a significance level of 95%, and a beta error accepted up to 20% with a power of study of 80%. Statistical analysis was performed with Statistical Package for the Social Science (SPSS) program for statistical analysis (IBM Corp. IBM SPSS Statistics for Windows, Version 21.0. Armonk, NY: IBM Corp.; Released 2012). Intraclass Correlation Coefficient (ICC) estimates and their 95% confident intervals were calculated using SPSS statistical package version 23 (SPSS Inc, Chicago, IL) based on a mean-rating (k = 2), absolute-agreement, and 2-way mixed-random model [21].

Results

During mechanical preparation, neither instrument fracture nor loss of working length was encountered in any of the teeth. A high degree of reliability was found between the two readings for transportation. The single ICC was 0.972 with a 95% confidence interval from 0.945 to 0.985 (F(59,59) = 81.420, p < 0.001) (Table 1), and was 0.999 with a 95% confidence interval from 0.998 to 0.999 (F(59,59) = 1725.500, p < 0.001) for centering ability (Table 2).

Transportation

At 3 mm, 6 mm, and 9 mm root level from the apex; there was no statistically significant difference between the two endodontic cavity designs, Mann–Whitney comparisons between both cavity designs revealed that teeth with CECs showed the statistically significantly highest median (IQR) amount of transportation at all levels. For each cavity design; there was no statistically significant difference between amounts of transportation between 3 mm, 6 mm, and 9 mm (Table 3).

As regarding the total amount of absolute transportation (median of the three root levels for each group); there was statistically significant difference between the two groups CECs showed the statistically significantly highest median amount of transportation 0.12 (0.07–0.16) while TECs showed the lowest amount of transportation 0.05 (0.03–0.06, p = 0.000) (Table 4).

Centering ability

At 3 mm, 6 mm, and 9 mm root level from the apex; there was no statistically significant difference between the two endodontic cavity designs. For each cavity designs; there was no statistically significant difference in term of centering ability between 3 mm, 6 mm, and 9 mm (Table 5). As regard the total amount of absolute centering ability (median of the three root levels for each group); there was no statistically significant difference between the two groups (p = 0.824) (Table 6).

Discussion

The emergence of minimally invasive dentistry [18], [19] has led to the modern concept of conservative endodontic access cavity; which targets the preservation of sound dentine by avoiding both complete de-roofing of the pulp chamber and avoiding over-flaring of canal orifices as well as avoiding aggressive dentine removal for shaping [20], especially around the pericervical dentin (located 4 mm above and below the crestal bone) where it acts as a buttress against structural flexure and ultimate fracture [22]. The leaning to cut smaller-sized access cavities was influenced by the use of illumination together with magnification, highly flexible instruments, and better imaging devices such as CBCT [11], while it is essential to shift the modern endodontic treatment toward a conservative ideology [23]; however, it is also necessary to

provide an adequate endodontic access to achieve optimal shaping as it is claimed that coronal interferences with CECs can increase the operative difficulties during canal instrumentation that may lead to root canal transportation.

Maxillary premolars were selected as several studies have reported that the presence of grooves on the furcation aspects of the buccal roots of maxillary premolars varied between 62% and 100% based on different evaluation methods [10], [24]. Excessive removal of dentin with thin canal walls present in maxillary premolars may lead to unnecessary weakening of the tooth and subject it to higher risk for root fracture.

In this study, shaping outcomes after instrumentation with HyFlex EDM single file were analyzed. The main proposed benefits of the single endodontic file system are cost effectiveness, prevention of cross contamination, and decreased instrument fatigue with single use of the instrument. The tested hypothesis was rejected, as the transportation observed in the TEC group was statistically higher than that observed in the TEC group at each analyzed level. It has been suggested that 0.15 mm apical transportation is acceptable [33]; however, if apical transportation exceeds 0.3 mm, it will have a negative impact on root canal filling [34]. In this study, although the median (IQR) of both groups was within the accepted limit, some specimens of the CECs particularly at the apical part of the canal exceeded this critical level, and the maximum value of 0.41 mm was considered not to be within the acceptable limit. This could be explained by the increased level of difficulty during instrumentation caused by coronal interferences and the absence of straight-line access that led to excessive instrument pressure against the outer aspect of the root canal curvature and to the increased number of pecking motions needed to reach the working length. Summing of canal transportation of the three root levels (3 mm, 6 mm, and 9 mm) of TEC group and comparing them to their correspondence in the CEC group showed significant difference with the better results achieved in TEC group. The result of the present study revealed that the type of access cavity influenced the shaping outcome in term of transportation and this result is in
line with the findings of Alovisi et al. [35] where they demonstrated significantly more canal transportation in CECs when compared to TECs, even when using CM instruments. Similar results could be observed in a study by Rover et al. [36] where canal transportation was significantly higher for the CEC group in the palatal canal of upper molars at 7 mm from the apical end than TEC group even when using M-Wire NiTi technology, probably because of the straight-line access in the TEC group. Regardless of the NiTi file system used, studies have shown the negative influence of CECs on the original canal anatomy especially on mandibular molars [12], [13].

In the analysis of centering ability, no significant difference was seen between TECs and CECs at the three tested levels, the summing of the three root levels (3 mm, 6 mm, and 9 mm) of TEC group showed better results when compared to the summing of the three root levels (3 mm, 6 mm, and 9 mm) of CEC group although there was no significant difference between them. These results may be due to the CM of HyFlex EDM file that can be pre-bent to follow the anatomy of the canal which was considered to be highly flexible and can be tailored to the original shape of the canal, in addition to the rectangular cross section of HyFlex EDM, which may provide a better centralization of the rotary file in the curved canal, this comes in agreement with Ozyurek and Yılmaz [37].

Finally, while the available evidence suggests that the most important factor impacting the survival of root-filled teeth is the amount of remaining dentin [38], [39], [40], [41] which highlights the significance of conserving dentin as a critical factor responsible for the fate of root-filled teeth, endodontic access cavity designs should be subjected to assessment of associated benefits and risks, as the elimination of intracanal bacteria to levels acceptable with periradicular tissue healing is paramount for root canal treatment success, the effect of minimally invasive endodontic approaches on the disinfection of root canals as well as the fracture resistance of endodontically treated teeth should be further assessed and considered before adopting this new design.

Conclusion

Based on the results of this in vitro study, HyFlex EDM single file performed similarly in CECs and TECs with regard to centering ability, while for transportation CECs negatively influenced the original canal anatomy.
